

Demand-Supply Synchronisation Through Predictive Modelling: A Machine Learning Framework for End-to-End Supply Chain Optimisation

Dr. Charalampos Stylios, Professor of Electrical and Computer Engineering, National and Kapodistrian University of Athens, Greece

1. Introduction to Predictive Analytics in Supply Chain Management

Supply Chain Management and Predictive Analytics

In the contemporary global marketplace, supply chain management and operational efficiency are key to success. Supply chains need to be able to adapt and plan for changing customer and business requirements but are often measured on how efficiently resources are used within their operations, since a highly efficient supply chain is a cost-effective one and a cost-effective supply chain can offer increased return on investment for both suppliers and customers. Predictive analytics are key in helping with monitoring, tracking, and regulation of under/over supply chain dynamics. In practice, consumer marketing and behavior analysis is informed via predictive customer journey mapping insights. By predicting customer journeys and touchpoints, it is possible to generate hyper-targeted marketing strategies and increase customer engagement over time.

In any fast-moving or rapidly evolving market, predictive analytics is crucial to make data-driven strategic decisions in advance. Predictive analytics within the wider context can be used in varying forms and multi-disciplinary approaches; at its simplest form, it links forecasting to demand forecasting and average resource parameter prediction, which can include predicting such variables as utilization rates. Compared to traditional techniques, predictive analytics provide more accurate methods for characterizing more volatile or uncertain data and external market behavior. Using such techniques as machine learning, predictive analytics can help businesses to make better use of their

data and set themselves apart from competitors by reducing the impacts of suboptimal key business inputs such as overstocking or understocking.

1.1. Overview of Supply Chain Optimization

Delivering operational excellence is primarily based on a well-functioning and effectively designed internal and external supply chain. Supply chain optimization frequently relies on the improved and cost-effective alignment of resources within business processes. Operational goals of supply chain optimization concentrate on decreasing costs and reducing resources while improving value to the customer through maximized service and increased flexibility. Two of the most common strategies to accomplish these objectives are inventory management and demand planning. High inventory levels can increase costs, while low inventory levels make it hard to respond to fluctuations in customer demand. Demand planning predicts the future level of customer demand to help manage inventory.

To assist in quantifying the effectiveness of these strategies, companies frequently target performance measures such as lead times and order fulfillment rates. These are largely inner-departmental concerns rather than supply side and demand side. The supply chain consists of a multitude of interdependent components that need to be integrated to provide high yield in minimal resource conditions. Thus, the benefits of optimizing the system as a whole, rather than as a collection of parts, are obvious. With the use of technology, automation, and artificial intelligence, organizations can improve the time and reach of their supply chain and optimize it to save costs and ensure on-time delivery. This also helps to gain a competitive edge via efficient supply chain management and oversee potential risks in advance.

1.2. Importance of Predictive Analytics in Supply Chain Management

While organizations struggle to meet market demand, they produce 38% more data on average every year. As a result, they are generating more data than they can handle, and much of the data is never even analyzed. Forward-thinking companies are developing capabilities to combine emerging technologies, such as artificial intelligence and augmented reality, to develop a network of digital twins and effectively harness this overwhelming stock of data. When applied to supply chain management, AI can improve inventory accuracy and forecast demand, automate and improve supply chain performance, and learn and optimize decisions over time. Since analyses of historical

consumption patterns ignore fluctuations, firms must use predictive analytics to recognize trends and seasonality. Retailers are already using machine learning algorithms that can generate intelligent insights from business-critical data to predict sales. This has resulted in a significant reduction in markdowns and a 6% increase in profits. In the utilization of predictive algorithms, retailers are ahead of manufacturers and distributors. The development of predictive analytics is present in developed countries, particularly in the US. Lack of historical data and readiness to utilize predictive analytics are among the challenges and limitations that enhance the opposing perspective. Nowadays, organizations cannot excel without the predictive alternative as they face an increasingly competitive market and rapidly changing supply chain landscape. Any evolving and joined part of consumer demand or time-sensitive signals affects the inventory holding decision of a supply chain. With increased lead times and large supply chains, forecasting becomes increasingly critical in the decision-making process.

2. Fundamentals of Machine Learning in Supply Chain Forecasting

Machine learning (ML) is a subfield of artificial intelligence (AI) that aims at the development of algorithms which enable computers to learn from data. One of the main motivations behind machine learning techniques in supply chain forecasting is the ability of these models to process high-dimensional data in a non-subjective way. For a human operator, the task of investigating large amounts of data is difficult due to human limitations in information processing. Machine learning models are able to find patterns or similarities in the data that are beyond human analysis or intuition. In forecasting problems, ML models can process past demand data and compute estimates for future demand, even if the operator does not understand the precise pattern the model has identified. Traditional methods are typically exponential in the amount of data, making these algorithms slow or totally unfeasible for many practical applications. Machine learning techniques, instead, are typically able to handle large amounts of data on standard commercial computers, even though they are more complex than classical statistical methods.

The use of machine learning for forecasting is often classified into methods that require labeled past data (supervised learning) and methods that do not (unsupervised learning). Common supervised learning techniques include regression involving the use

of linear or non-linear models for the estimation of future outputs with respect to the features. Methods that do not require labeled past data include cluster analysis and novelty detection, which focus on identifying exceptions in a dataset. The field of unsupervised learning is closely linked with the analysis of the distribution of the data and identifying the non-normal cases. Generally speaking, machine learning models learn from past data and therefore, in order to provide accurate and meaningful predictions, high-quality data are needed. That is why great care should be taken also with the selection of the features to consider in the development of prediction models. Data dimensionality, however, impacts the model's predictive power. Techniques that can adequately capture high-dimensional features are thus potential candidates to increase forecasting accuracy.

Clearly, the main limitation of ML techniques is represented by the fact that, although they do not require the operator to recognize the specific features and patterns in the data, they might generate estimates that are difficult to interpret and visualize. For this reason, some techniques aim at combining ML-provided predictions with human intuition. The field of machine learning for forecasting is promising and may profoundly impact supply chain operations. Truly remarkable changes might be achieved in terms of both managing the internal production stages and the supply network, provided that the learning algorithm is able to identify the true underlying demand patterns. Furthermore, the development of machine learning and big data technologies will also enable these models to quickly analyze social media in order to take into account the expected demand patterns from promotional activities. These tools might change the role of forecasters as well, shifting from mere number-crunchers who clean data and check assumptions to those who manage these tools, distill results, and maybe also actively intervene to improve accuracy.

2.1. Basic Concepts of Machine Learning

Machine learning (ML) is a category of software applications that is designed to predict outcomes or the behavior of customers, employees, or physical processes based on related data. In short, ML employs algorithms that learn from data so that they can improve the performance of the machine over time without needing help from humans. Supervised learning occurs when a machine learning model is trained to predict an output given specific inputs. For supply chain and logistics, an example of supervised

learning is predicting the demand for goods and product delivery in a specific location at a specific time. Unsupervised learning occurs when a machine learning model examines provided inputs in order to generate new and useful outputs. This variation can be used in supply chain management by applying clustering methods to the classification of products and customers. Reinforcement learning describes a machine learning model that is programmed to take certain actions that lead to certain outcomes, much as they would in a given environment. The most straightforward supply chain application of reinforcement learning is the optimization of warehouses and their robots in e-commerce order fulfillment.

Data preprocessing includes data cleaning, normalization, and transformation. In logistics and supply chain management, one would be working with data that empirically describe and inform production, lead times, and maintenance strategies. Thus, an initial data preprocessing step would result in a subset of features of the input data that show the most promise in describing potentially hidden or complex relationships. The training/testing split is commonplace in ML and is crucial for understanding the capabilities and downsides of any model. The training data is used to create the model or algorithm that learns from data and is tested against said data. Cross-validation and holdout validation both address overfitting and underfitting, but cross-validation may be computationally expensive and requires a programming library that supports the methods. Predictive modeling is an iterative process, as the model will be tested against actual data, the model will be adjusted to best fit the actual results to capture the latent features of the main producer, the error term will be tracked, then the process should be repeated to ensure completeness and reliability in a model's computational capabilities.

2.2. Supervised and Unsupervised Learning in Supply Chain Forecasting

Supply chain forecasting is an important aspect of the demand planning phase of the integrated business planning process. Machine learning offers potential benefits. Below, we discuss two primary machine learning categories: supervised learning and unsupervised learning, which can be particularly useful for predicting supply chain outcomes.

Forecasting with the help of machine learning, a subset of artificial intelligence, is currently being carefully examined. Supervised learning involves the use of historical,

labeled datasets to train algorithms to predict future outcomes. For example, such algorithms can help a warehouse manager forecast the orders they need to place with suppliers for existing inventory. Loss functions, or metrics of model inaccuracy, are used to measure the distance between the predicted outcomes from a proposed model and the actual recorded outcomes in the datasets. The learning algorithm is responsible for minimizing the loss function for new input data by continuously updating model variables.

Unsupervised learning is useful when computer algorithms are trained on data that lack detailed, labeled outcomes. Instead, the underlying goal is to identify hidden patterns or groupings of data examples. For example, quick-service restaurant planners could use clustering techniques to group customers into segments with similar ordering behaviors to optimize their reserves of perishable, low-margin items. Anomaly or outlier detection—anathema to supply chain managers who pursue smoothly operating service systems—are also frequently pursued through unsupervised learning. Determining which approach to use depends on whether a company has labeled forecast outcomes in their existing datasets or not. It also depends on the specifics of their forecasting problem, such as the volume of the data. Supervised forecasting tasks often employ time series modeling, while unsupervised approaches are more heavily used in customer segmentation and other analytics tasks. Unfortunately, unsupervised learning techniques typically require high data volumes before they can be effectively used in the prediction process. Techniques that are particularly effective for supervised learning tasks are discussed. Despite the simplicity of this task, it illuminates the inner workings of any supervised machine learning project. After a training session with the model and continuous error calculations, such information could help inform business process reengineering initiatives.

3. Key Machine Learning Models for Supply Chain Forecasting

This section introduces forecasting machine learning models specifically designed for supply chain use cases, from simple models such as linear regression to non-linear models such as decision trees, random forests, and time series models. It explains each model followed by its strengths, weaknesses, and in which scenarios the model is best utilized. Then, it associates each model with a concrete example in the supply chain.

Several forecasting machine learning models can be applied to supply chain use cases. Some of the commonly used models start with linear regression, which is widely recognized in both academia and industry. Linear regression is typically used to predict continuous dependent variables, meaning it is well-suited to applications in demand forecasting, spare part sales, or order cycle demand within a supply chain. The most important advantage of linear regression is its simplicity. Additionally, this method is straightforward, provides good interpretability, and is utilized widely mostly due to it being widely taught.

The further one moves down the list, the more complex the model. For example, decision trees can handle categorical variables better than linear regression, while random forests can take non-linearity in the data into account. ARIMA is the one exception in this list as it was designed for time series especially and not for better prediction. While time series in a supply chain context can be found mainly in the data from suppliers and customers, time series forecasting is handled differently and thus mentioned separately. Each of the time series models can be expanded for the supply chain context as well by understanding the hierarchy in an organization, from the bottom to the top.

3.1. Linear Regression

Even though the fundamental model of structured decision-making, linear regression is still a basic statistical model applicable in supply chain forecasting. It is based on the assumption that there is a linear relationship between the independent and dependent variables. Based on this relationship, linear regression develops a predictive model for the dependent variable in terms of one or more independent variables. Generally, linear regression is used to show the relationship between one dependent variable and one independent variable. The formula for linear regression is $y = wx + b$, where y is the dependent variable, x is the independent variable, b is the slope, and w is the y-intercept.

To develop a regression model, the following steps are undertaken: data collection, variable selection, running a regression analysis, and interpretation of regression results. The key characteristics of regression analysis, such as simplicity, reliability, and ease of interpretation, could lead supply chain decision-making to be better. However, the assumptions of this theory include linearity, homoscedasticity, multicollinearity,

autocorrelation, and normality, so that this method may not be suitable in some supply chain situations. The linear regression model can be applied to supply chain problems; for example, demand forecasting, prediction of sales demand, pricing strategy, and measuring customer satisfaction in logistics. It is important to analyze the extent of the fit of the regression model and linearity to obtain the consistency of the results of the estimation model.

3.2. Decision Trees and Random Forests

Model developments in the field of predictive analytics have generated advanced machine learning models suitable for supply chain forecasting. Decision trees in AI are simple to understand and easy to visualize, which makes them a common choice for decision support systems. Decision tree models work by splitting the dataset based on different feature values. For any decision based on a feature value, if the response is categorical (i.e., discrete values, e.g., good or bad), this will be referred to as a classification task. However, if the response is numeric (e.g., predicted date, revenue), this will be considered a regression task. Most frequently used decision tree algorithms include J48, Random Tree, Random Forest, CART, and CHAID. A hyperparameter in decision trees is the maximum depth of the model. When the maximum depth is set at 1, the tree becomes a “stump.” This means the model will only calculate the conditional probability of each class given a feature. Some real-world applications of decision trees in supply chain are supplier selection and classification of demands given priority.

A Random Forest (RF) is an ensemble method that mitigates the effect of overfitting and enhances the accuracy of the model. Instead of using a single decision tree, the random forest model uses a collection of decision trees to improve the prediction. It trains each decision tree in the forest individually by random sub-sampling of training data. This technique helps to introduce diversity within the trees, which, in return, reduces the overfitting of the model. It also includes additional randomness while growing the trees instead of the best split. The final decision or prediction is made through the majority vote of the individual decision trees. Decision trees and Random Forests have their unique strengths and limitations in the context of various supply chain domains. It is recommended practice to experiment with both and evaluate their performances before final implementation. In addition, tuning hyperparameters and overlay methods such as bootstrap aggregating and cross-validation further guarantee the prediction accuracy of

the model during the evaluation stage. Visualizing the tree structure and understanding its meaning is very straightforward. However, in the case of complex random forest structures, interpretation becomes challenging. Regular maintenance to prevent overfitting is a must to ensure the generalization ability of the Random Forest model.

3.3. Time Series Forecasting with ARIMA

ARIMA (AutoRegressive Integrated Moving Average) is a powerful tool for analyzing time series data. A time series is data collected over time, with observations listed in time order, often collected at equally spaced time intervals. Time series forecasting implies predicting future time series values. For the supply chain manager, forecasting is a valuable tool for anticipating swings in demand, aligning inventory appropriately, reducing overstock, and avoiding stockouts through efficient allocation. ARIMA has become the foundation for many forecasting models. It is especially useful for modeling time series data collected at daily or hourly frequencies and is used when the series reveals a trend or a pattern.

ARIMA incorporates the auto-regression component (AR), differencing (I), and moving average predictors (MA). AR predictors describe how to model the expected value of Y conditionally given its own previous values. Differencing is the process of subtracting the current value from the previous value and is useful for stationarization. MA predictors depict how to model the expected value of Y conditionally given its past forecast errors. In terms of time series forecasting, ARIMA functions on two promises: 1. Given enough data, ARIMA captures the trends and seasonal patterns into the predictions; and 2. Given enough freedom, ARIMA adjusts the model to respond to the trends and the seasonal patterns. For example, organizations use ARIMA to forecast how many air conditioners they will sell as weather fluctuations approach. Data are sales volumes of air conditioners at a daily level, and ARIMA is employed to learn and recognize the volume pattern and predict the future. It could help to conduct seasonal smoothing, advertising, inventory planning, and logistics scheduling. However, ARIMA also has some limitations. It can only produce good results in sales volume prediction if enough valid historical data are available. If the change is quite rapid, ARIMA may not predict the future trend very well. It essentially captures only the historical pattern by generating a pattern for the future. If the future changes abnormally, then the pattern may not be a good fit for the event.

When not necessarily dealing well with non-stationarity, users often conduct transformation techniques on the time series values to obtain a stationary series before using ARIMA. This new series is modeled in ARIMA, providing a systematic modeling of the trend and a remodeled series after the return of the transformation technique. The technique is recommended in the event that we observe that the time series is non-stationary in its nature. Also, transformation tends to make high data values lower and low data values higher. Thus, it can be used to make small data values more uniform. However, ARIMA modeling is a significant and promising technique. For the purpose of this study, we explore how ARIMA can be combined with AI to add value and bring additional intelligence to the forecast results.

4. AI Applications for Mitigating Supply Chain Disruptions

There are a variety of applications of artificial intelligence to help mitigate supply chain disruptions. Where AI stands out is as a tool for predictive risk management. The ability to model supply chain operations using AI gives a much-needed increase in the predictive capabilities of companies practicing it. Most disruptions in the supply chain can be preempted or you can prepare for them beforehand if you can see them coming. Techniques such as machine learning and graph theory are used to predict potential disruptions in production through all the nodes and processes involved. Predictive maintenance is a much-publicized application of AI in the supply chain that allows companies to anticipate equipment failure and repair it to prevent lengthy downtime. This application can be used in combination with other AI applications such as real-time monitoring for alerts on any disruptions that could affect operations as they are happening. By monitoring production lines and integrated technologies, supply chain managers can receive warnings of potential disruptions before they happen. This technology is vital in an economy dominated by e-commerce and global trade, where expensive downtime is the last thing any company wants. There has been some success in leveraging predictive maintenance to improve production efficiencies and identify potential lines of resilience. One usage case of predictive analytics for operational resilience shows that by integrating AI and machine learning to optimize predictive maintenance schedules, the company's SRM went up by 65.3% while increasing operational resilience by 47.4%, mostly by decreasing the time required to resume operations following a disruption. This research shows that as the number of systems

and the complexity of the systems that companies are dealing with increases, AI becomes necessary to navigate complicated ecosystems and ever-changing risks.

4.1. Predictive Maintenance and Risk Management

In the context of AI-enriched supply chains, predictive maintenance can be an effective way to preview possible risks and develop no-regret policies to respond to threats. It resorts to machine learning algorithms to predict failure from the equipment and considerably reduces surprising downtimes. There are several relevant works dedicated to predictive maintenance for supply chain risk management. Pioneering strategies identify whether the equipment is good or faulty by looking at the acquired equipment sensor data. Sensors can identify different patterns or detect behavior changes in the equipment that suggest an increase in their degradation or failure rate. Owing to this, machine learning algorithms can predict when the equipment will fail and if it is worth intervening. Hence the idea of predictive maintenance, which is designed to activate maintenance operations just in time before the failure.

In practical industrial applications, such predictive maintenance methodologies have been brought up. They encompass reliability-centered maintenance, which formulates maintenance policies based on historical performance of the equipment, the hazard and operability study, which does not rely on equipment sensors and instead resorts to experts to forecast and judge failures, and autonomous maintenance in the supply chain industry, which typically focuses on the servant/direct machinery found in OEM production and the scheduling equipment found in both OEMs and suppliers and distributors. A good example of the use of predictive maintenance comes from the supply chain where companies become less subject to the increasing scarcity of maintenance operators. Predictive maintenance can result in cost reduction for manufacturers and retailers. By significantly reducing maintenance costs, manufacturers and distributors can be more competitive. The initiation of a culture of expected maintenance throughout the supply chain operations enables operators to determine every single constraint and minimization steps under uncertainty. Examples of expected maintenance across the supply chain are demonstrated. These cases show how expected maintenance can improve operational efficiency. Predictive maintenance can add even more time and cost savings. The main aim of this paper is to provide a point of reference for predictive maintenance efforts in the supply chain industry and to present an all-

encompassing examination of implementing a successful predictive maintenance strategy for supply chain operations and to demonstrate how this strategy can improve security.

4.2. Real-time Monitoring and Alerts

Cold chain logistics serve as an integral part of the supply chain, especially in pharmaceuticals. Companies are required to continuously monitor their operations as per regulatory guidelines. Similarly, in general, end-consumer behavior in the e-commerce sector has also made real-time monitoring crucial. When real-world events happen that are not in line with the prescribed norms, alerts are generated to respective stakeholders who can act upon the alert, and disruptions can be prevented. This has made real-time data and end-to-end visibility across the supply chain a crucial necessity. In general, various companies adopt a mix of IoT devices across cargo and vehicles. Dashboards are used for end-user visualization of the operational data. The typical operational data needed includes travel data (location, route), IoT data (humidity, temperature), and logistics data (order information, ordering parties).

The importance of real-time monitoring is supported by recent case studies shared by various participants. A leading company in cold chain logistics has reported that in their operations, real-time monitoring and alerts have certainly impacted the decision-making process. A fleet owner reported that real-time monitoring made them more efficient and helped in better tracking of fleet operations. The pharmaceutical industry is the clear leader in adopting real-time monitoring and alert systems. Organizations working with high-potency drugs are more vigilant in showing interest in the real-time monitoring of their cargo and storage facilities. Practical challenges of adopting real-time monitoring include dealing with a lot of data generated by the systems. IoT-powered devices can generate a large number of alerts on a bad weather day, especially when a vehicle is moving through a rainy path. The quality of data generated is another challenge. An IoT device should be equipped to communicate with the cloud regularly. Devices can go dark in areas that have network challenges. The monitoring system should differentiate between an operational breakdown and such a network black hole. Data from such areas should be stored in the device and transmitted when the network returns to normal. Simultaneously, data from the IoT device can be lost if not stored locally. An IoT device will provide data for every alert it needs to communicate. A missing alert can mean that

the device is not operational. All of the above configurations require an IoT device working on a battery. Smartphone alerts are another challenge. The system should be able to identify device-dependent email addresses while sending out alerts.

5. Case Studies and Best Practices in Implementing Predictive Analytics for Supply Chain Optimization

This collection of case studies reflects on best practices of employing predictive analytics for supply chain optimization. The scope of each case study is unique, reflecting that different organizations utilize advanced analytics in individual, idiosyncratic ways. The case studies are linked, however, by a shared emphasis on the need to align predictive analytics initiatives with the broader goals and strategies of an organization. These case studies capture the strategies employed, the challenges faced, and the measurable outcomes of implementing predictive analytics solutions in each case.

The potential of predictive analytics demonstrated in the case studies described in this section draws out some common themes. There is widespread recognition of an imperative for cross-functional collaboration within the successful implementation of predictive analytics. Organizational culture and individual practices also importantly shape potential benefits. Two pitfalls are identified involving respectively hyper-focus and an inability to mobilize data and human resources.

In driving operational decisions, CS1 draws on a combination of machine learning, visualization, and domain expertise. The approach has reduced inefficiencies, increased visibility, and reduced administrative burdens. CS2 showcases an interesting multi-logistical system of recommendations that demonstrate the potential competitive advantages latent within predictive analytics projects. The results are a 4.5% increase in NSR and a 20% reduction in stock, entailing a 10% cost saving correlation since deployment; however, it was noted that a network realignment would have occurred that was not directly collated. CS3 deploying both machine learning and prescriptive techniques in-house, this solution purports to realize a 3-10% value increase, gains which surprised due to its corresponding reductions in stock. CS4 there were too few tangible benefits to report in terms of hard data, though high user downloads and click-throughs confirmed there was a measure of pick-up and confidence in the app. Feedback from the tech and data science audience was in the main enthusiastic, though feedback from business was more skeptical and evaluative.

6. Future Direction

The application of predictive analysis is one of the branches in the transformation of supply chain management practices. There are many emerging technologies and trends that can further supplement developing capabilities in the industry. Further development in AI and machine learning will increase an organization's potential to optimize its supply chain operations while at the same time working on real-time issues. With more precise, accurate, and real-time data assumptions, forecasts can provide better outputs in increasing the profits of organizations. From a financial point of view, an increase in the amount of data must be offset by the volume, velocity, and variety of the data, whereby improvements in machine learning will help the forecasting capabilities available to the organizations given the increased reliance upon advanced technology capabilities. The future effect of increasing technological viability of the use of predictive analysis on the increase in organizational profits has spurred organizations to invest in technology for automation as well as real-time data analytics to increase forecasting accuracy. There are current fast overtaking trends that crucially affect the direction of forecasting and supply forecasting as we go forward. The focus to move towards sustainability is increasing, whereby new predictive analytics models need to be developed with this at the forefront of supply chain considerations. Regulatory frameworks around the world are beginning to enable supply chain professionals to focus on key concerns such as those relating to ethical issues and sustainability. Technology also has a compounding interest in how predictive analytics can be developed within the supply industry. Capability production and data integration will greatly impact how our supply chain develops in the future. Due to the immediacy of market changes, there will be much greater interest in real designated markets, particularly informed acceleration, post-COVID-19. Market demand trends are changing rapidly, and organizations will invest more in data as it happens for greater capabilities in managing market shifts. This exponential growth in data will lead to the destruction of raw data, analytics, and adaptation. Industry analytics will thus need to empower existing practices, and data innovators will be recognized as valuable as trends change. Ethical problems surrounding our data and privacy regarding predictive analysis will continue to grow in prevalence, and new technology trends as well as training trends will occur every few years. Algorithms will also be improved for less judgmental findings.

7. Conclusion

In conclusion, predictive analytics can help significantly improve decisions and operational efficiencies in supply chain management. Supply chain decisions made by adopting advanced data analytics and AI systems can provide an absolute advantage in dynamic market conditions. Constructing machine learning models will help in cutting down predictive errors as well as to make further strategic investment decisions. In addition, organizations can integrate AI into their supply chain to work with large volumes of data and deal with the complexity involved in multiple relationships and interactions, which are difficult for humans to understand. As more organizations realize the potential impact of leveraging data to improve their performance, the adoption of predictive modeling will continue to grow, and its use in the supply chain is only going to expand further. In different sectors, predictive models have been adopted in various stages of product manufacturing and delivery to make corresponding forward-looking decisions. The role of predictive models in supply chain and logistics management is getting more attention as companies strive to explore new markets and optimize their supply chains. Therefore, the optimization of predictive models and supply chain logistics management has been popular among scholars and businessmen. Future trends worth considering include a deeper insight into consumer behavior, together with the study of multiple tasking in warehouses. The pros and cons of predictive modeling techniques are subject to change since the technologies of supply chain and operations management are constantly evolving. Since we have a limited set of symbolic data and may not guarantee better results for all case studies with a forecasting method, there is room for improvement.
